Abstract

Limits on v_{μ} -> v_{τ} and v_{μ} -> v_{e} neutrino oscillations have been determined using a massive fine-grained calorimeter exposed to a narrow-band neutrino beam at Fermilab. We have searched for neutrino oscillation candidates by selecting events with the quasi-elastic topology. By having a visible energy which is predominately in the lepton sector, this type of event has sensitivity to neutrino oscillations and a signature which is indicative of the incident neutrino flavor. From cuts on the event energy allowed by the properties of the incident narrow-band beam, we have determined the following 90% confidence limits for the neutrino mass squared difference Δm^2 at maximum mixing: v_{μ} -> v_{τ} , Δm^2 < 8 eV²; \overline{v}_{μ} -> \overline{v}_{τ} , Δm^2 < 6.5 eV²; v_{μ} -> v_{e} , Δm^2 < 1.8 eV²; and \overline{v}_{μ} -> \overline{v}_{e} , Δm^2 < 3.1 eV².

(I) Introduction

Several properties of the neutrino remain undetermined even after roughly 30 years of experimentation. The basic question concerning the CP structure of the neutrino remains unanswered - whether the neutrino is a Majorana or a Dirac particle. The mass of the neutrino is poorly determined, and the possible mixing of neutrinos belonging to different lepton families remains a possibility. Given the fundamental nature of these questions, it is important to gather more data on the mass and possible mixing of different neutrino flavors.

If the neutrino has a finite mass and if there are finite differences between the masses of neutrinos of unlike flavors, there can be neutrino flavor mixing. Thus, a beam initially composed of only one neutrino flavor can become a mixture of flavors determined by the neutrino mass squared difference, the mixing angle, the propagation distance, and the beam energy. Limits on the occurrence of this neutrino mixing can lead to very sensitive constraints on mass differences between neutrino species. In the case of mixing between only two neutrino species i, the probability that an initial neutrino species i with mass m_i oscillates into a neutrino species j with mass m_i is given by 2,3 :

$$P(v_i - v_j) = \sin^2(2\theta) \sin^2(1.27\Delta m_{ij}^2 L/E_v),$$
 (1)

where $\Delta m_{ij}^2 = m_i^2 - m_j^2$ in eV². L is the distance from the neutrino source in kilometers, E_v is the neutrino energy in GeV, and θ is an unknown mixing angle. In this experiment we have determined an upper confidence level limit for the probability of the neutrino flavor oscillations $P(v_{\mu} -> v_{\tau})$ and $P(v_{\mu} -> v_{e})$. We use these upper limits to exclude regions in the Δm^2 versus $\sin^2(2\theta)$ plane⁴. The L/<E $_{\eta}$ > region of this experiment is roughly 0.023 km/GeV.

Two experimental techniques have been used to detect the presence of neutrino oscillations. In the first technique a search is made for a discrepancy in the measured neutrino flux using detectors located at various distances from the neutrino source, or for a difference between the measurement and the expected neutrino flux in a single detector. Such a "disappearance" experiment typically involves minimal final state identification. A detailed understanding of the incident neutrino flux is necessary to obtain a good limit. The second technique involves the attempt to detect the anomalous presence of a given neutrino species in a beam of known composition. This type of "appearance" experiment necessarily requires significant final state discrimination to signal the appearance of a different neutrino flavor in a beam of known composition.

The data in this study were collected with the neutrino detector located in Lab C at Fermilab during a narrow-band beam run. The neutrino detector was

designed to measure neutral current interactions ^{5,8,7}, but with its high modularity it can also detect and measure the kinematics of quasi-elastic neutrino-nucleon scattering events. By imposing kinematic constraints allowed by the incident narrow band neutrino beam, a direct separation of the oscillation candidate events from background events was performed and limits on neutrino oscillations were determined.

The selection of quasi-elastic events in a narrow band beam has the advantage of minimizing the visible energy in the hadronic sector of the neutrino interaction. While the hadronic energy spectrum may vary from flavor to flavor due to flavor dependent form factors, the whole range of hadronic energy is expected to be no more than a few hundred MeV⁸. Thus, we searched for neutrino oscillations with final states which could have resulted from any of the following three reaction chains:

Case A: v_{μ} oscillation into v_{τ} . The v_{τ} undergoes a quasi-elastic interaction, v_{τ} + N -> τ^- + P, followed by the decay, τ^- -> $\mu^ \overline{v}_{\mu}$ v_{τ} . (See Figure 1a)

Case B: v_{μ} oscillation into v_{τ} . The v_{τ} interacts quasi-elastically with the nucleon by the reaction, v_{τ} + N -> τ^- + P, followed by the decay, τ^- ->e $^ \overline{v}_{\rm e}$ v_{τ} . (See Figure 1a)

Case C: v_{μ} oscillation into v_{e} . The v_{e} scatters via the quasi-elastic channel, v_{e} + N -> e + P. (See Figure 1b)

For each of the three reaction chains described above the antineutrino case was also considered.

In Cases A and B we searched for a single muon or electron, respectively, with an event energy significantly smaller than the narrow-band beam energy. In Case C a search is made for a single electromagnetic shower with an energy consistent with the spectrum of the narrow-band beam. This clean event topology, with the straightforward candidate event selection according to missing energy, enabled the systematic errors of this search to be well controlled and the upper bounds on the various neutrino flavor oscillations to be directly estimated.

A brief description of the experimental apparatus is given in Section 2. Section 3 describes the data analysis, and Section 4 presents the conclusions.

(II) Experimental Apparatus

The fine-grained neutrino detector located in Lab C at Fermilab was built to study deep-inelastic neutrino-nucleon scattering by the means of the weak neutral-current interaction using the Fermilab narrow-band neutrino beam⁹. The neutral-current study required the neutrino detector to be highly segmented to determine both the energy and angle of the recoil hadronic shower. Because of this highly segmented construction and a flexible trigger design, the apparatus could also detect and measure quasi-elastic neutrino-nucleon scattering. The fine-grained design therefore made the device suitable for a neutrino oscillation search where the quasi-elastic channel, with its clean energy constraints in a narrow-band beam, could be exploited. Recoil protons could be observed as low as 300 MeV kinetic energy and electron showers could be distinguished from hadronic showers. The outgoing muon momentum was reconstructed with an iron toroid spectrometer placed behind the calorimeter. Thus both muon-neutrino and electron-neutrino quasi-elastic scattering could be measured.

(1) The Calorimeter:

The calorimeter⁵ is based on 608 polypropylene flash chambers and 37 proportional tube chambers. The device is 19 meters long and $3.6x3.6m^2$ in cross section. The calorimeter mass is 340 metric tons and has an average density of 1.4 g/cm³. The neutrino target material consists of plastic extrusions filled with sand and steel shot in alternating layers which makes the detector massive but with a low atomic number. Fig. 2 gives an overview of the detector.

The construction of the calorimeter is modular. The flash chambers are used to determine the type of neutrino interaction and to measure the shower energy and angle of the reaction products. The proportional tube chambers provide the trigger for the flash chambers and furnish an independent measurement of the shower energy. The flash chambers are assembled in units of 4 in the sequence of U-X-Y-X. The U-X-Y flash chambers are constructed with their cells at 100-0-80 degrees about the horizontal plane. The proportional tube chambers have wires alternating in the horizontal and vertical directions and are located at intervals of 16 flash chamber planes. These chambers sample the shower in 10 cm lateral segments (about a Moliere radius).

The longitudinal shower sampling of the flash chambers is 22% of a radiation length and 3.1% of an absorption length. The proportional tube chambers sample the shower in the longitudinal direction every 3.5 radiation lengths and every 0.49 absorption lengths. The fine granularity permits electron showers to be separated from hadronic showers with only a few percent hadronic shower contamination for energies up to 50 GeV. The pattern recognition capabilities allow recoil protons from quasi-elastic scattering to be detected and the outgoing muon tracks from $v_{\rm H}$ -nucleon quasi-elastic

scattering to be easily reconstructed.

(2) The Muon Spectrometer

The muon spectrometer⁵ consists of three 7.31 meter and four 3.66 meter diameter magnetized iron toroids located just downstream of the flash chamber – proportional tube calorimeter. There are roughly 7 meters of magnetized iron in the spectrometer. Four gaps between the toroids are instrumented with proportional chambers which determine the position of the muon track to an RMS spatial precision of about 0.73 cm. These chambers are constructed in a double layer with a half-cell-offset to resolve the left-right ambiguity. A muon momentum resolution is achieved which is approximately the multiple scattering limit of the spectrometer $\sigma_{\rm P_{II}}/\rho_{\rm II} < 15\%$.

(3) The Narrow-Band Beam

The neutrino energy spectrum and the absolute flux are known in the narrow-band beam. The beam is operated by momentum-selecting pions and kaons with a momentum bite of $\Delta Po/Po \approx 10\%$ using a magnetic beam transport system⁹. The momentum-selected pions and kaons decay in a 340 meter long evacuated beam pipe producing a neutrino energy spectrum with two distinct energy bands corresponding to the two meson decays. A schematic diagram of the beam layout is shown in Fig. 3.

The energy of the incident neutrino of the narrow-band beam depended on the mass of the decaying meson and on the angle of the neutrino with respect to the secondary beam direction. The energy was determined from the kinematics of the secondary particle (pion or kaon) decay by the following:

$$E_v \approx (m^2 - m_{\mu}^2)/(m^2/P_0 + P_0\theta_v^2),$$
 (2)

where m is the pion or kaon rest mass, m_{μ} is the muon rest mass, P_{0} is the pion/kaon central momentum, and θ_{υ} is the angle of the neutrino with respect to the parent beam direction in the laboratory frame. The angle of the neutrino was estimated from the radius of the event vertex about the centroid of the incident neutrino beam. A typical measured energy-versus-radius correlation is shown in Fig. 4. The data are muon-neutrino quasi-elastic events taken with the narrow-band beam set to focus 165 GeV/c positive secondaries. The kaon and pion energy bands are apparent.

The narrow-band pion and kaon secondary beam momentum was set at165, 200, and 250 GeV/c to focus positive secondaries for the neutrino data. The antineutrino data were taken at 165 GeV/c with the beam set to focus negative secondaries.

(III) Data Analysis

In this section we describe the analysis procedure for each of the three reaction chains given above. The analysis involved searching for a single muon or electron shower consistent with a v_{τ} or a $v_{\rm e}$ quasi-elastic neutrino-nucleon interaction. To select the quasi-elastic topology we required the hadronic energy of the candidate events to be less than 1 GeV in the flash chamber calorimeter. A further condition was imposed by requiring that there be a clearly identified muon track or electron shower emerging from the primary vertex.

A v_{τ} quasi-elastic event, where the τ^{\pm} has decayed into either a muon and two neutrinos or an electron and two neutrinos, has a predicted event signature which resembles the ordinary quasi-elastic scattering of a muon or an electron neutrino. However the reconstructed energy of the event will be smaller than expected since there will be energy carried away by the undetected neutrinos from the τ^{\pm} decay. The missing energy can be calculated by comparing measured event energy to the incident neutrino energy predicted energy-versus-radius correlation of the narrow-band beam. requiring that there be a significant amount of missing energy we can distinguish the $v_{\rm H}$ -> $v_{\rm T}$ neutrino oscillation candidates from the background events. Only leptonic decays of the charged z-lepton were considered since the hadronic decays of the z-lepton have an event topology which is difficult to separate from the abundant muon-neutrino neutral-current events.

(1) Case A: v_{\perp} -> v_{τ} Decay Muon Channel

In the decay muon channel (Case A) we searched for the possibility of a muon-neutrino oscillating into a tau-neutrino which interacts quasi-elastically with a target nucleon followed by the produced τ^{\pm} lepton decaying into a μ^{\pm} $v_{\mu}v_{\tau}$. The branching ratio for this decay mode has been measured to be 17.6 \pm 0.6%. The signature of the quasi-elastic v_{τ} -nucleon interaction followed by the τ^{\pm} decay is a single outgoing muon track with an energy smaller than that expected from quasi-elastic scattering in the narrow-band beam. The missing energy corresponding to the unobserved neutrinos in the τ^{\pm} decay is computed by comparing the outgoing muon energy, which carries essentially all of the event energy for an ordinary muon-neutrino quasi-elastic interaction8, with the expected neutrino energy computed from the energy-versus-radius correlation of the narrow-band neutrino beam.

The quasi-elastic events satisfied a trigger condition which required the muon to reach the back chambers of the muon spectrometer (roughly 7 meters of iron), and a total energy deposition in the calorimeter of less than 10 GeV. The outgoing muon track could deposit up to 5 GeV in the calorimeter. Therefore

only a relatively small fraction of the incident neutrino energy was allowed to be deposited in the hadronic sector. The efficiency of this trigger condition was about 80% for true v_{μ} quasi-elastic events and was measured by calibration beam muons analyzed to simulate the trigger.

The final selection of the neutrino oscillation candidates required that the outgoing muon have an energy $\rm E_{\mu} > 10$ GeV. Additional requirements were imposed to insure that the radius of the event vertex was within 150 cm of the beam central axis and that there be less than 30 flash chamber hit cells excluding the muon track within a 50 cm radius of the event primary vertex. The latter cut corresponds to an upper bound of hadronic energy of about 1 GeV. Fig. 5 shows a typical event selected by these criteria.

While we have made stringent cuts on the amount of energy deposited around the primary vertex to select quasi-elastic events, we have a contamination of "almost quasi-elastic" events where the low lying nucleonic resonances have been excited. An additional complication arises from complex target effects (our calorimeter mass is mostly composed of SiO₂ and Fe, with a smaller component of Al and hydrocarbons) which lead to final state interactions of the outgoing recoil nucleon. These effects do not alter our result because of electron-muon-tau universality. According to this assumption, at the high energies of this experiment where lepton mass effects are small, the nucleon resonance excitation by muon neutrinos will be the same as for electron or tau neutrinos. Furthermore the complex target final state interactions are assumed to be independent of the incident neutrino species. Since we internally normalize our data these effects will cancel.

As a check that our data are in agreement with our expectations, we compared the reconstructed momentum transfer Q^2 between the outgoing muon and the incident neutrino with our Monte Carlo simulation for antineutrino events in the pion band energy region. The result is shown in Fig. 6 where we see that the agreement between the data and the Monte Carlo simulation is good. The antineutrino data set has been chosen to avoid the background of inverse muon decay $(v_{\parallel} e^- \rightarrow \mu^- v_e)$.

To separate neutrino oscillation candidates from ordinary background events a cut was made on the missing energy which arises from the undetected neutrinos of the τ -lepton decay. Therefore most of the υ_{τ} events are expected to be below the pion energy band. We refer to this region as the signal region "S" in Fig. 4. The pion band region, referred to as the background region "B" in the figure, is the domain where most of the ordinary υ_{μ} quasi-elastic events are expected. We have avoided searching for neutrino oscillation candidates in the region between the pion and kaon energy bands. In that region there is a large flux of neutrinos from the three body decay modes $\kappa_{\mu3}$ and κ_{e3} which makes the computation of the missing event energy critically dependent on the knowledge of the neutrino flux shape and composition.

The quantitative separation of the v_{μ} -> v_{τ} oscillation signal region, S, from the background region, B, is accomplished by selecting events using the scaled energy variable:

$$y_{\mu} = (E_{\upsilon}^{\pi}(r) - E_{\mu})/E_{\upsilon}^{\pi}(r), \qquad (3)$$

where ${\rm E}_{\nu}^{\ T}({\rm r})$ is the predicted average neutrino energy at a given radius arising from pion decay, and ${\rm E}_{\mu}$ is the measured muon energy. Note that positive values of ${\rm y}_{\mu}$ correspond to missing event energy. The ${\rm y}_{\mu}$ distributions of the data at the four narrow-band beam settings are compared with the corresponding Monte Carlo simulations of ordinary muon-neutrino quasi-elastic scattering in Fig. 7. The signal region, S, was defined by the cut ${\rm y}_{\mu} > 0.6$ which optimized the sensitivity to $v_{\mu} > v_{\tau}$ oscillations while minimizing the number of true muon-neutrino quasi-elastic events. The background region was determined by the cuts $-1.0 < {\rm y}_{\mu} < 0.6$. These definitions were chosen from a study of the Monte Carlo simulation which required the signal region to contain a factor of 100 less v_{μ} quasi-elastic events than the background region. In the signal region the overall efficiency for v_{τ} oscillation events was 15 times higher than the efficiency for ordinary v_{μ} quasi-elastic events.

Table I summarizes the number of observed events (NB) found in the background region B, the number of events (NS) in the signal region S, and the calculated efficiencies $\epsilon_{\mu}{}^{B}$, $\epsilon_{\mu}{}^{S}$ for detecting a υ_{μ} quasi-elastic event in the two kinematic regions, respectively. The efficiencies for detecting a υ_{τ} quasi-elastic event with the decay mode τ^{\pm} -> $\mu^{\pm}\upsilon_{\mu}\upsilon_{\tau}$ in these two regions are given by $\epsilon_{\tau}{}^{B}$ and $\epsilon_{\tau}{}^{S}$. These efficiencies were determined by a Monte Carlo simulation which took into account the acceptance, momentum resolution, and the narrow-band beam characteristics. The muon trigger efficiency was not included in the analysis of the decay muon channel since it cancels in our determination of the oscillation limit.

There were three major backgrounds which contaminate the v_{τ} quasi-elastic candidates. These backgrounds were either included in the Monte Carlo simulation of the experiment or were explicitly subtracted.

1) The first background was due to muon-neutrinos which originate from π -or K-decays before the momentum selection of the narrow-band beam. By closing the collimator in the secondary pion/kaon beam while taking data the absolute normalization of this background was fixed. The spectrum shape was computed by a Monte Carlo simulation 12 . The Monte Carlo simulation was compared with the data and, within statistics, the predicted closed collimator background was found to be consistent with the observed spectrum. Using the normalized Monte

Carlo simulation, the ratio of the closed collimator background to the standard muon-neutrino flux was 0.4% for the antineutrino setting, and 0.6% for the pion band neutrino beam settings.

- 2) The second background was due to muon-neutrinos which originated from the three body decay mode $K_{\mu3}$. The kinematics of the three body decay can give rise to neutrinos with an energy less than the pion-band energy. Quasi-elastic events induced by these muon-neutrinos will therefore have an apparent missing energy. The magnitude of the background was estimated from the Monte Carlo beam simulation to be 0.2% of the pion band muon-neutrino flux for the antineutrino setting and 0.6% for the neutrino beam settings.
- 3) The third background consisted of events from the inverse muon decay reaction $(\upsilon_{\mu}+e^-->\mu^-+\upsilon_e)$ which contributed a signal for incident neutrinos but not for incident antineutrinos by additive lepton number conservation. The detection efficiencies for this process are denoted by $\varepsilon_{\rm I}^{\rm S}$, and $\varepsilon_{\rm I}^{\rm B}$ in Table I. In a separate analysis the observed number of events from this process corrected for detection efficiency was 23 ± 8 events.

To set limits on the neutrino oscillation mode of Case A, we define the ratio $R_{\mu}^{\ \tau}$ to be the number of events of υ_{τ}^{+} N-> τ^{-} + P followed by the decay τ^{-} -> $\mu^{-}\upsilon_{\tau}\upsilon_{\mu}$ (likewise for the corresponding antineutrino case) over the number of ordinary muon-neutrino quasi-elastic events, N_{μ} . The observed total numbers of events N^{S} and N^{B} detected in the two regions S and B are expressed by adding the number of υ_{τ} quasi-elastic events given by $N_{\mu}R_{\mu}^{\ \tau}\varepsilon_{\tau}^{\ S,B}$, the number of ordinary υ_{μ} quasi-elastic events which is denoted by $N_{\mu}\varepsilon_{\mu}^{\ S,B}$, and the number of inverse muon decay events (υ_{μ} + e $^{-}$ -> μ^{-} + υ_{e}) $N_{I}\varepsilon_{I}^{\ S,B}$. Thus:

$$N^{S} = N_{\mu}(R_{\mu}^{\tau} \varepsilon_{\tau}^{S} + \varepsilon_{\mu}^{S}) + N_{I} \varepsilon_{I}^{S}$$
(4a)

$$N^{B} = N_{\mu}(R_{\mu}^{\tau} \epsilon_{\tau}^{B} + \epsilon_{\mu}^{B}) + N_{l} \epsilon_{l}^{B}. \tag{4b}$$

Equations (4a) and (4b) are then solved for the ratio R_{μ}^{τ} defined above, and the number of quasi-elastic events N_{μ} corrected for the detection efficiencies defined above. The result is:

$$R_{\mu}^{\tau} = (\epsilon_{\mu}^{S} - \eta \epsilon_{\mu}^{B})/(\eta \epsilon_{\tau}^{B} - \epsilon_{\tau}^{S})$$
 (5)

where η = (N^S-N_I \epsilon_I^S)/(N^B-N_I \epsilon_I^B), and the corrected number of muon-neutrino quasi-elastic events is:

$$N_{\mu} = (N^{S} - N_{I} \epsilon_{I}^{S}) / (R_{\mu}^{\tau} \epsilon_{\tau}^{S} + \epsilon_{\mu}^{S}). \tag{6}$$

The results for R_{μ}^{τ} and its 90% confidence upper limit $R_{\mu}^{\tau}_{90\%}$ are given in the last two columns of Table I. We see that $R_{\mu}^{\tau}_{=0.04}$ (0.015) and $R_{\mu}^{\tau}_{90\%}$ =0.11 (0.066) for v_{μ} (\overline{v}_{μ}).

(2) Case B: v_{μ} - v_{τ} Decay Electron Channel

In this channel we searched for the possibility of a muon-neutrino to oscillate into a tau-neutrino which interacts quasi-elastically with the target nucleon followed by the tau-lepton decaying into an electron and two neutrinos $(\tau^\pm \to e^\pm \ v_e \ v_\mu)$. The signature for this process is an electromagnetic shower which satisfies the energy deposition trigger in the calorimeter (E_calorimeter > 10 GeV) but with an energy less than that expected from the narrow-band beam pion band. An additional criterion which diminished the deep inelastic muon-neutrino neutral current background was imposed by requiring the transverse momentum about the incident neutrino axis be small (P1 < 2 GeV/c) since almost all quasi-elastic events are at small Q². A typical $v_e + N \rightarrow e^- + P$ quasi-elastic candidate event selected by these criteria is shown in Fig. 8.

There is a significant neutral-current background in Case B arising from υ_{μ} -nucleon deep-inelastic scattering. These events can have dense hadronic showers which therefore imitate the expected event characteristics. Some reduction of the neutral-current background is achieved by making energy and transverse momentum cuts on the recoil electromagnetic shower. But these cuts are not sufficient to entirely eliminate this large background. Therefore a software filter was designed to distinguish electromagnetic showers from hadronic showers. This filter utilized the characteristics that electromagnetic showers are small in their transverse dimension, dense, and are not surrounded by visible tracks in the flash chamber calorimeter. By using calibration electron and hadron showers, we determined that the filter was >99% efficient for electron showers above 10 GeV and had a hadronic shower rejection efficiency which ranged from 96% at 10 GeV to 99% at 75 GeV.

To estimate the hadronic background from muon-neutrino neutral-current deep-inelastic scattering we assumed that the fraction of neutral-current deep-inelastic scattering events which has a large electromagnetic component is the same fraction as in charged-current deep-inelastic scattering. The hadronic background was therefore determined by applying the filter to all charged-current deep-inelastic scattering events. In this study charged-current events were selected with the same cuts as were applied to the oscillation candidates. These cuts required that the events have a radius about the central neutrino beam axis of less than 120 cm for good lateral shower containment and a shower energy $E_{\rm S} > 10$ GeV. An additional cut was made in the scaled energy

variable defined by:

$$y_e = (E_v^{\pi}(r) - E_S)/E_v^{\pi}(r).$$
 (7)

requiring that $y_e > 0.2$, where $E_v^{\pi}(r)$ is the average incident energy from the pion band at a radius r given by the energy-versus-radius correlation of the narrow-band neutrino beam. The y_e cut demanded that there be missing energy consistent with $v_{\mu} -> v_{\tau}$ oscillation followed by the τ^{\pm} decay into $e^{\pm} v_e v_{\tau}$. An additional requirement was imposed that the transverse momentum of the shower (P_{\perp}) with respect to the neutrino direction be less than 2 GeV/c to suppress deep-inelastic neutrino-nucleon scattering.

Other backgrounds include neutral current coherent π^0 production from nuclei $(v_\mu + N - v_\mu + N + \pi^0)^{14}$, coherent σ production from nuclei $(v_\mu + N - v_\mu + N + \sigma)^{15}$, and resonant π^0 production¹¹. The coherent π^0 process contributes a significant background to Case B since it has a sizable cross section compared to the quasi-elastic cross section and a (1-y) dependence $(y = E_\pi o/E_v^{\ T}(r))$ which allows the π^0 energy to be in the signal energy region below the pion neutrino band. Furthermore, the π^0 electromagnetic showers are indistinguishable from electron showers in our calorimeter. The coherent single σ process is expected to have a small cross section (about 0.5% of the coherent σ cross section at 50 GeV) and therefore it does not contribute much background. The resonant σ production is expected to produce electromagnetic showers at quite low energies (< 1 GeV) since the σ from this process comes from N* decay which is produced at low Q² by form factor effects. Therefore this background will be strongly suppressed since it will produce electromagnetic showers which are largely below the threshold of the energy deposition trigger.

We have considered two other backgrounds: (1) electron-neutrinos (from K_{e3} decay) that scatter quasi-elastically off nucleons (v_eN), and (2) muon-neutrinos which elastically scatter off electrons in the target ($v_{\mu}e$). Both of these reactions give rise to electron showers which have the characteristics of the oscillation candidates for which we are searching.

The oscillation limit is computed by subtracting the backgrounds from the neutral-current events which have identified electromagnetic showers (NC $_{\rm em}$ data sample). The largest background arises from the neutral-current deep-inelastic scattering events as was discussed above. This background is followed in significance by coherent π^0 production by the neutral current. We estimate that the coherent π^0 process contributes 4.2 background events for incident neutrinos and 3.1 background events for incident antineutrinos. By a Monte Carlo simulation the $(\upsilon_e {\rm N})$ and $(\upsilon_\mu {\rm e})$ backgrounds $^{16.17}$ both contribute

0.68 events for incident neutrinos; and 0.14 and 0.31 for antineutrinos, respectively. We have neglected the coherent σ process and resonant π^0 production.

The first two columns in Table II show the number of charged-current (CC) and neutral-current (NC) events found in the sample before the electromagnetic shower filter cuts. In the third and fourth columns, the electron filter cut and the transverse momentum cut have been imposed. We denote the resulting numbers of events after these cuts by $\rm CC_{em}$ and $\rm NC_{em}$, respectively. The neutral-current deep-inelastic background was estimated by determining the number of charged-current events which satisfy the electron filter, $\rm CC_{em}$ corrected for the ratio, $\rm r_u$, of neutral-current to charged-current events.

As in the muon channel case, we define R_e^{τ} as the ratio of the number of events n_{τ} of the type v_{τ} + N -> τ^{-} + P with the τ^{-} subsequently decaying into e^{-} $\overline{v}_{e}v_{\tau}$ over the number of events n_{μ} of the type v_{μ} + N -> μ^{-} + P. The limit for incident antineutrinos was treated in the same manner. The value of $R_e^{\tau} = n_{\tau}/n_{\mu}$ can be calculated by using the relation which expresses the number of observed v_{τ} candidates, $n_{\tau} \varepsilon_{\tau}^{e}$, in terms of the number of observed electromagnetic events corrected for the four backgrounds discussed above. ε_{τ}^{e} is the detection efficiency calculated by Monte Carlo methods for finding an electron from the decay of the τ in a quasi-elastic reaction. This relation is:

$$R_e^{\tau} = (NC_{em} - r_{\mu}CC_{em} - n_{\pi}o - n_{\upsilon eN} - n_{\upsilon \mu e})/n_{\mu}\epsilon_{\tau}^{e}, \qquad (8)$$

where n_{μ} is the number of v_{μ} quasi-elastic events found in the previous muon channel analysis (N $_{\mu}$) corrected for the trigger efficiency (80%) and the less restrictive radius cut (r<120cm), and r_{μ} is the ratio of the neutral-current to charged-current events found from our deep inelastic scattering data sample before applying the filter and P_{\perp} cuts, but after the correction for the K_{e3} background. $n_{\pi}o$ is the calculated number of coherent π^{0} events accepted by the cuts. $n_{\upsilon eN}$ is the calculated number of background v_{e} quasi-elastic signature events. $n_{\upsilon \mu e}$ is the estimated number of background v_{μ} - electron elastic events. Referring to the last two columns of Table II we find that the ratio R_{e}^{τ} was determined to be 0.0112 and -0.0134 for the neutrino and antineutrino cases, respectively. The corresponding 90% confidence upper limits are 0.030 and 0.012.

(3) Case C: v_{μ} -> v_{e} Electron Neutrino Oscillation Channel

In the electron neutrino oscillation channel-Case C we searched for the possibility of a muon-neutrino (v_{μ}) oscillating into an electron-neutrino (v_{e}) , where the electron-neutrino interacts quasi-elastically with a target nucleon. The signature for this reaction sequence is a single electromagnetic shower in the calorimeter with no significant missing energy and a small transverse momentum with respect to the incident neutrino beam axis.

Electromagnetic showers were selected from the deep-inelastic sample (NC+CC events) with the aid of the previously defined filter. The oscillation data sample was formed by the events that passed the electromagnetic shower filter with the additional requirements that $-0.2 < y_e < 0.2$, where y_e is defined by equation (7) above, and the transverse momentum P_\perp of the electron shower about the incident neutrino direction be less than 1.5 GeV/c. The number of events that passed these cuts is given in Table III.

The v_{μ} -> v_{e} oscillation limit is computed in the same manner as in Case B described above. Defining $R_{e}^{\ e}$ as the ratio of the number of electron-neutrino quasi-elastic scattering candidate events to the number of events from the process v_{μ} + N -> μ^{-} + P (and the corresponding antineutrino reactions), we have the relation:

$$R_{e}^{e} = (NC_{em} - r_{\mu}CC_{em} - n_{\tau o} - n_{\upsilon eN} - n_{\upsilon \mu e}) / n_{\mu} \varepsilon_{e}^{e}, \qquad (9)$$

where all of the quantities in this equation are defined in the same manner as in Case B above. Note that $\epsilon_e^{\ e}$ is the efficiency for detecting an electron-neutrino quasi-elastic event with the P $_{\perp}$ < 1.5 GeV/c. In this case the number $n_{\upsilon\mu e}$ of background events from the muon neutrino-electron elastic scattering is 0.20 and 0.12 for the incident neutrino and antineutrino beams, respectively. The number $n_{\upsilon eN}$ of electron neutrino quasi-elastic scattering events is 3.97 for incident neutrinos and 0.62 for incident antineutrinos. The coherent π^0 process contributes 0.59 and 0.27 events for neutrinos and antineutrinos, respectively. Referring to Table III, the upper limits are $R_e^{\ e}$ = -0.0096 (0.0055) and the 90% confidence level upper limits are $R_e^{\ e}$ = 0.007 (0.02) for the neutrino (antineutrino) cases.

(IV) Determination of the Oscillation Upper Limits

By interpreting the upper limits given in Tables !, II, and III in terms of upper limits from neutrino oscillations in the channels discussed above, we obtain a limit on the oscillation probability $P(v_{\mu}^{-}>v_{\tau})$ given by equation (1) through the relation:

$$\int dQ^{2}dE_{\upsilon}\phi(E_{\upsilon}) P(\upsilon_{\mu} - > \upsilon_{\tau})d^{2}\sigma^{\tau}/dQ^{2}dE_{\upsilon}$$

$$R^{\tau} = ----\Gamma, \qquad (10)$$

$$\int dQ^{2}dE_{\upsilon}\phi(E_{\upsilon}) d^{2}\sigma^{\mu}/dQ^{2}dE_{\upsilon}$$

where $\phi(E_{\upsilon})$ is the incident neutrino flux, E_{υ} is the incoming neutrino energy in GeV, $d^2\sigma^{\tau,\mu}/dQ^2dE_{\upsilon}$ is the quasi-elastic differential cross section for υ_{τ} and υ_{μ} , respectively. Γ is the branching ratio for the leptonic decays of the τ -lepton under consideration. Equation (10) can be solved numerically in terms of the neutrino flavor mixing angle θ and the mass squared difference Δm^2 for the oscillating pair of neutrino flavors.

To achieve the best statistical significance in the testing of the $\upsilon_{\mu}\text{--}\!\!>\!\!\upsilon_{\tau}$ oscillation hypothesis we computed a combined upper limit for R for both the muon decay channel (Case A) and the electron decay channel (Case B). In the analysis of the upper limits R and N are determined by the maximum likelihood technique. The likelihood function was computed from the product of the separate likelihood functions of the muon decay channel (Case A) and the electron decay channel (Case B). The resulting upper limits for R at the 90% confidence level are 0.034 for the neutrino beam and 0.024 for the antineutrino beam.

Fig. 9 shows the result for the combined tau-decay muon and electron channels (Case A and B). In the limit of maximal mixing with the muon and electron channels combined, the upper limit for $v_{\mu} -> v_{\tau}$ is $\Delta m^2 < 8$ eV², and for the antineutrino case $\overline{v}_{\mu} -> \overline{v}_{\tau}$, $\Delta m^2 < 6.5$ eV². In the limit where Δm^2 becomes large we find that the mixing angle has to satisfy the following limits: for $v_{\mu} -> v_{\tau}$, $\sin^2 2\theta < 0.20$; for $\overline{v}_{\mu} -> \overline{v}_{\tau}$, $\sin^2 2\theta < 0.15$.

In Case C, where we searched for the possibility of v_{μ} -> v_{e} and \overline{v}_{μ} -> \overline{v}_{e} oscillations, we interpret the results from Table III through equation (10) to obtain the following results: for v_{μ} -> v_{e} oscillation Δm^{2} <1.8 eV² and for \overline{v}_{μ} -> \overline{v}_{e} Δm^{2} <3.1 eV² for maximal flavor mixing. Our result for the excluded Δm^{2} versus $\sin^{2}2\theta$ region is shown in Fig. 10. In the large Δm^{2} region we find

for v_{μ} -> v_{e} , $\sin^2 2\theta$ <0.015; for \overline{v}_{μ} -> \overline{v}_{e} , $\sin^2 2\theta$ <0.04. We have set Γ =1 in equation (10) since there are no branching ratios involved.

(V) Conclusion

We have set limits on the probabilities $P(v_{\mu} -> v_{\tau,e})$ for a muon-neutrino to oscillate into either a tau-neutrino or an electron-neutrino. The experimental sensitivity to the neutrino oscillations was optimized by selecting quasi-elastic neutrino-nucleon scattering in a narrow-band neutrino beam. This has the advantage of emphasizing the lepton sector which is unique to each incident neutrino flavor. Furthermore, the energy constraints of the narrow-band neutrino beam enabled simple energy cuts to be applied to the data to isolate the oscillation candidates. This technique allows for a straightforward analysis. No evidence for neutrino oscillations was found.

The best limit on v_{μ} -> v_{τ} oscillations from an exclusive-type experiment is $\Delta m^2 < 0.9$ eV² (90% confidence limit) from E531 at Fermilab¹8.19. For the antineutrino case, \overline{v}_{μ} -> \overline{v}_{τ} , the best limit is from the ITEP-FNAL-MICH experiment²0 which finds $\Delta m^2 < 2.2$ eV². The 90% confidence level upper limit for the v_{μ} -> v_{e} oscillation channel in an exclusive type experiment has been found to be $\Delta m^2 < 0.16$ eV² from a BEBC experiment²¹. In the antineutrino case, \overline{v}_{μ} -> \overline{v}_{e} , a limit has been set of $\Delta m^2 < 1.0$ eV² from the GGM-PS collaboration²². A recent BNL experiment of Ahrens et al.²³ finds the limit $\Delta m^2 < 0.43$ eV² for maximal mixing. Our limits in both the tau and the electron oscillation channels are somewhat less restrictive but our technique is quite different from that of the other experiments.

The issues of neutrino flavor nonconservation and neutrino mass are still open. Very sensitive searches for neutrino flavor nonconservation have been performed by the means of neutrino oscillations. To date, no convincing evidence has been given for the existence of the effect 24 . Further experimentation with a much greater sensitivity is needed to make a significant contribution to this subject 25 .

Acknowledgments:

We would like to thank the National Science Foundation and the U.S. Department of Energy for funding this work. The experiment would not be possible without the fine technical support of FNAL, MIT, and MSU.

Table I Summary of the muon channel (Case A)

The details of the calculation of the limits of a muon-neutrino to oscillate into a tau-neutrino where the tau-lepton decays into an muon and two neutrinos are given. The column marked "mode" denotes the neutrino oscillation mode. The background region B is the π -band region defined by the $-1.0 < y_{\mu} < 0.6$ cut. The signal region S is defined by the cut $y_{\mu} > 0.6$. N^B is the number of events found in the B-region. $\epsilon_{\mu}{}^B, \; \epsilon_{\tau}{}^B, \; \epsilon_{l}{}^B$ are the efficiencies defined in the text for the B-region. N^S is the number of events found in the S-region, and $\epsilon_{\mu}{}^S, \; \epsilon_{\tau}{}^S, \; \epsilon_{l}{}^S$ are the corresponding detection efficiencies. $N_l{}^B$ and $N_l{}^S$ are the observed number of inverse muon decay events in the two regions, and are given by $\epsilon_l{}^B N_l{}^S$ and $\epsilon_l{}^S N_l{}^S$, respectively. Note that $\epsilon_l{}^B$ and $\epsilon_l{}^S$ for antineutrinos are identically zero since the inverse muon decay reaction is forbidden by additive lepton number conservation. The upper limits are given by the columns $R_{\mu}{}^{\tau}$ and $R_{\mu}{}^{\tau}_{90\%}$, where the former is the ratio of the number of v_{τ} quasi-elastic events with the τ^{\pm} -> μ^{\pm} v_{τ} v_{μ} decay to the number of v_{μ} quasi-elastic events, and the latter is the 90% confidence level upper limit of $R_{\mu}{}^{\tau}$.

Table II

Summary of the electron decay channel (Case B)

A summary of the muon-neutrino to tau-neutrino oscillation case where the tau decays into an electron and two neutrinos is shown. The column marked "mode" denotes the neutrino flavor oscillation mode. CC and NC are the number of charged-current and neutral-current deep-inelastic scattering events used to determine the dense neutral-current background. The heading marked "Before Filter" shows the number of events before the electromagnetic filter was applied but after the y_e cut was made. The ratio r_{μ} =NC/CC is used in equations (8) and (9). The column "After All Cuts" denotes the number of events after the filter and all cuts were applied. The number of coherent π^0 background events satisfying the cuts is given by $n_{\pi}o$. The number of quasi-elastic signature events corrected for the software and trigger efficiency is given by n_{μ} . The efficiency to detect a v_{τ} quasi-elastic event is ϵ_{τ}^{e} . R_{e}^{τ} is the ratio of v_{τ} to v_{μ} quasi-elastic events, and $R_{e}^{\tau}_{90\%}$ is the 90% confidence limit of R_{e}^{τ} .

Before Filter After All Cuts											
mode	CC	NC	cc _{em}	NC _{em}	n _{TC} o	n_{μ}	ϵ_{τ}^{e}	Re [₹]	Re [*] 90%

Table III
Summary of the electron neutrino channel (Case C)

The upper limits on the muon-neutrino to oscillate into an electron-neutrino are listed. The column marked "mode" denotes the oscillation channel considered. CC and NC are the number of charged-current and neutral-current deep inelastic scattering events, respectively. The "Before Filter" and "After Filter" columns pertain to before and after the electromagnetic filter cut. The coherent π^0 background is given by $n_{\pi}o$. The number of muon-neutrino quasi-elastic events used for the rate normalization is given by n_{μ} . $\epsilon_e^{\ e}$ is the efficiency to detect a v_e quasi-elastic event, $R_e^{\ e}$ is the ratio of v_e to v_{μ} quasi-elastic events, and $R_e^{\ e}$ gos the 90% confidence upper limit of $R_e^{\ e}$.

Figure Captions:

Figure (1a): Symbolic representation of a v_{μ} oscillating into a v_{τ} with the v_{τ} interacting by quasi-elastically scattering off a target nucleon. The τ^{\pm} -lepton decays into either μ^{\pm} v_{μ} v_{τ} , or e^{\pm} v_{e} v_{τ} .

Figure (1b): Symbolic representation of a v_{μ} oscillating into a v_{e} with the v_{e} interacting by quasi-elastically scattering off a target nucleon. Note that the outgoing lepton, in this a case an electron, indicates the incident neutrino flavor.

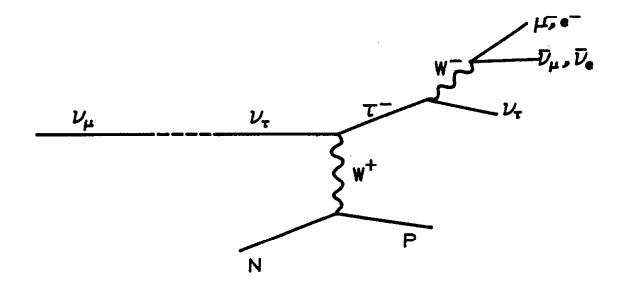

Figure (2): A schematic drawing of our 340 metric ton calorimeter is shown. The toroid muon spectrometer located behind the calorimeter is used to analyze the momenta of outgoing muons from the neutrino interaction. Shown below is a detailed schematic of one module of the calorimeter. A module is made from 16 flash chambers layered between — plastic extrusions alternately filled with sand and steel shot. Proportional tube chambers placed at intervals of every 16 flash chambers provide the trigger for the flash—chambers, and furnish an independent measure of the energy deposited in the calorimeter.

Figure (3): The layout of the dichromatic neutrino beam at Fermilab. Shown is a schematic outline of the beam transport system which defines the momentum of the secondary pions and kaons of the beam, the secondary beam monitors, and the location of our experiment at Lab C. Note that the drawing is not to scale, although the relevant distances are indicated. For simplicity the other neutrino detectors in the beam line have not been shown.

Figure (4): The energy-versus-radius correlation of the dichromatic neutrino beam as measured by the outgoing muon energy for muon-neutrino quasi-elastic events. The data are from the +165 GeV/c beam setting. The $\upsilon_{\mu}^{->\upsilon_{\tau}}$ oscillation domain is indicated by the S-region. The region where the ordinary muon-neutrino quasi-elastic events are confined is indicated by the area B in the figure. Shown are the boundary lines defined in the text by the limits -1.0 < υ_{μ} < 0.6. The predicted average neutrino energy $E_{\upsilon}^{\ \pi}(r)$ used in the text is indicated by the line E(r).

Figure (5): Computer display of a typical muon-neutrino quasi-elastic event. Shown are the x-view chambers around the primary vertex. The numbers on the outside of the figure indicate the dimensions of the event in meters. Each dot in the display is a hit cell of a flash chamber. A recoil proton and an outgoing muon track are clearly visible emanating from the primary vertex. The proton recoil kinetic energy is approximately 1 GeV. The track intersecting the recoil proton is believed to be an accidental cosmic ray.

- Figure (6): The $\mathbf{Q^2}$ distribution of muon-neutrino quasi-elastic scattering data is compared to the Monte Carlo simulation. The data are from the antineutrino beam setting to avoid the inverse muon decay background. The quasi-elastic events have been selected to be in the oscillation background region B defined in the text. The data are indicated by the points with error bars and the Monte Carlo simulation is denoted by the histogram.
- Figure (7): The y_{μ} -distribution for quasi-elastic events versus theMonte Carlo simulation. The signal region S and the background region B as defined in the text are shown. (a) -165 GeV/c dichromatic train setting. (b) +165 GeV/c dichromatic train setting. (d) +250 GeV/c dichromatic train setting.
- Figure (8): A typical electron-neutrino quasi-elastic scattering event. For simplicity only the x-flash chamber view is shown. Each dot in the figure is a 5x5 mm² hit cell. The recoil shower is identified as an electromagnetic shower because of the dense energy depostion with no visible tracks within the shower body. A small recoil proton stub coming from the primary vertex is visible which has an estimated kinetic energy of 300 MeV. The size of the event is indicated by the grid on the border of the diagram marked in meters.
- Figure (9): The Δm^2 versus $\sin^2 2\theta$ correlation for the combined upper limit at the 90% confidence level of Case A and Case B of this experiment is shown. The excluded region is to the upper right of the curves. Shown is the upper limit found in this experiment for the neutrino case v_{μ} -> v_{τ} (upper curve), and the upper limit for the antineutrino case, \overline{v}_{μ} -> \overline{v}_{τ} (lower curve).
- Figure (10): The Δm^2 versus $\sin^2 2\theta$ correlation for the upper limit at the 90% confidence level for v_{μ} - v_{e} oscillations Case (C) of this experiment. The lower curve is for the neutrino case v_{μ} -> v_{e} and the upper curve is for the antineutrino case \overline{v}_{μ} -> \overline{v}_{e} . The excluded region is shown in the upper right part of the graph.
